# How to get SNP data

- DNA chip up to ~2 million SNPs
- Capture the *pattern* of all SNPs
- Identify SNP patterns among group of individuals (genetic affiliation)
- Why are these patterns of genetic affiliation important?

# Genetic affiliation of SEA people

- How different are SEA people from each other in the genetic sense?
- We can place boundaries according to ethnicity, geography and languages
- Medical benefit when knowing your genetic affiliation

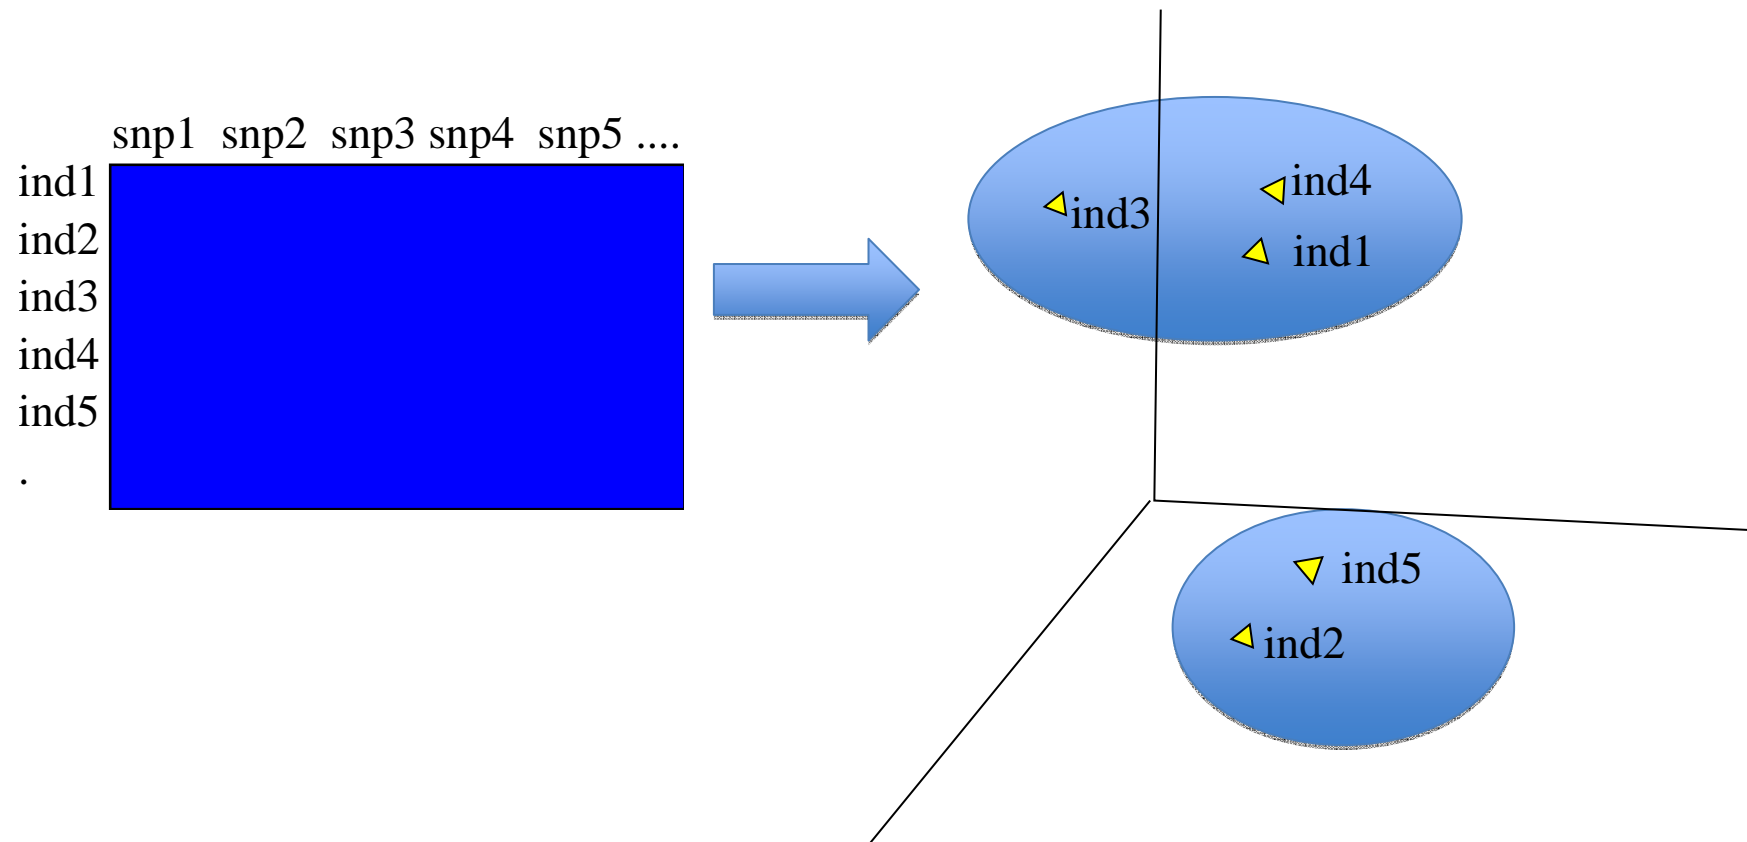

# Where the data come from?

- SEA data from Vietnamese, Cambodian, Chinese, Japanese, Thais, Indonesian from Xing et al. dataset
- Thalassemia patients minor and major from Thailand
- Depressive disorder patients from Thailand

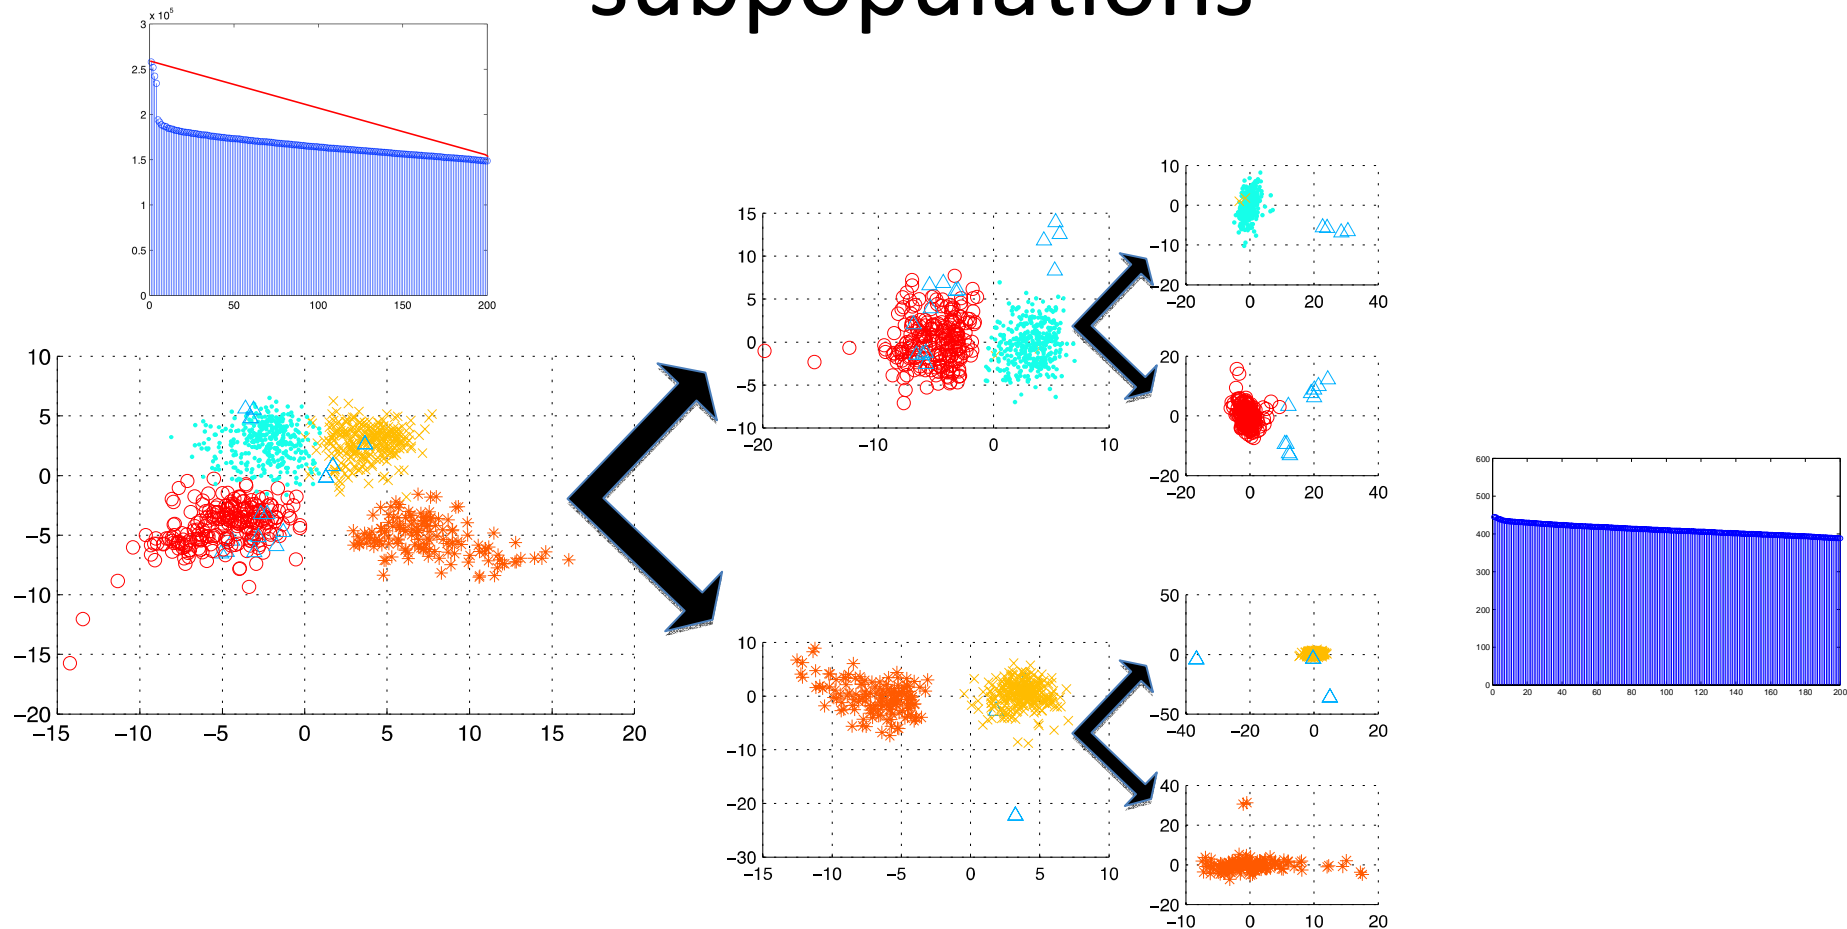

# Grouping Individuals

- Based on SNP patterns
- Using PCA-based technique to group them
- Subpopulation defines a group of *unrelated* individuals in which the variation among those individuals contains nothing more than what would be expected from random

# How we identify the subpopulations

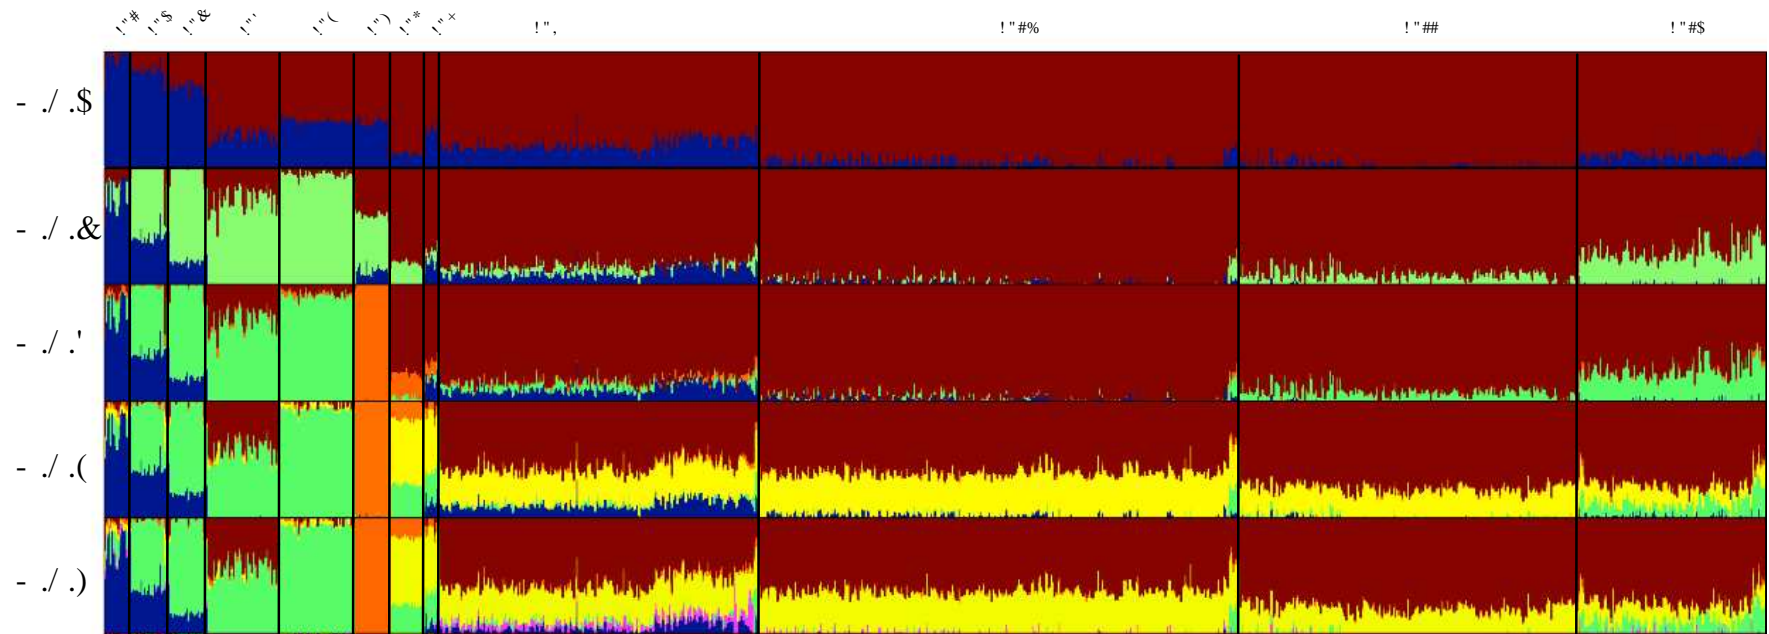

# ipPCA method for resolving subpopulations

Study of large and highly stratified population datasets by combining iterative pruning principal component analysis and structure. Limpiti T, Intarapanich A, Assawamakin A, Shaw PJ, Wangkumhang P, Piriyaopngsa J, Ngamphiw C, Tongsimas S. [BMC Bioinformatics. 2011 Jun 23;12:255.](#)

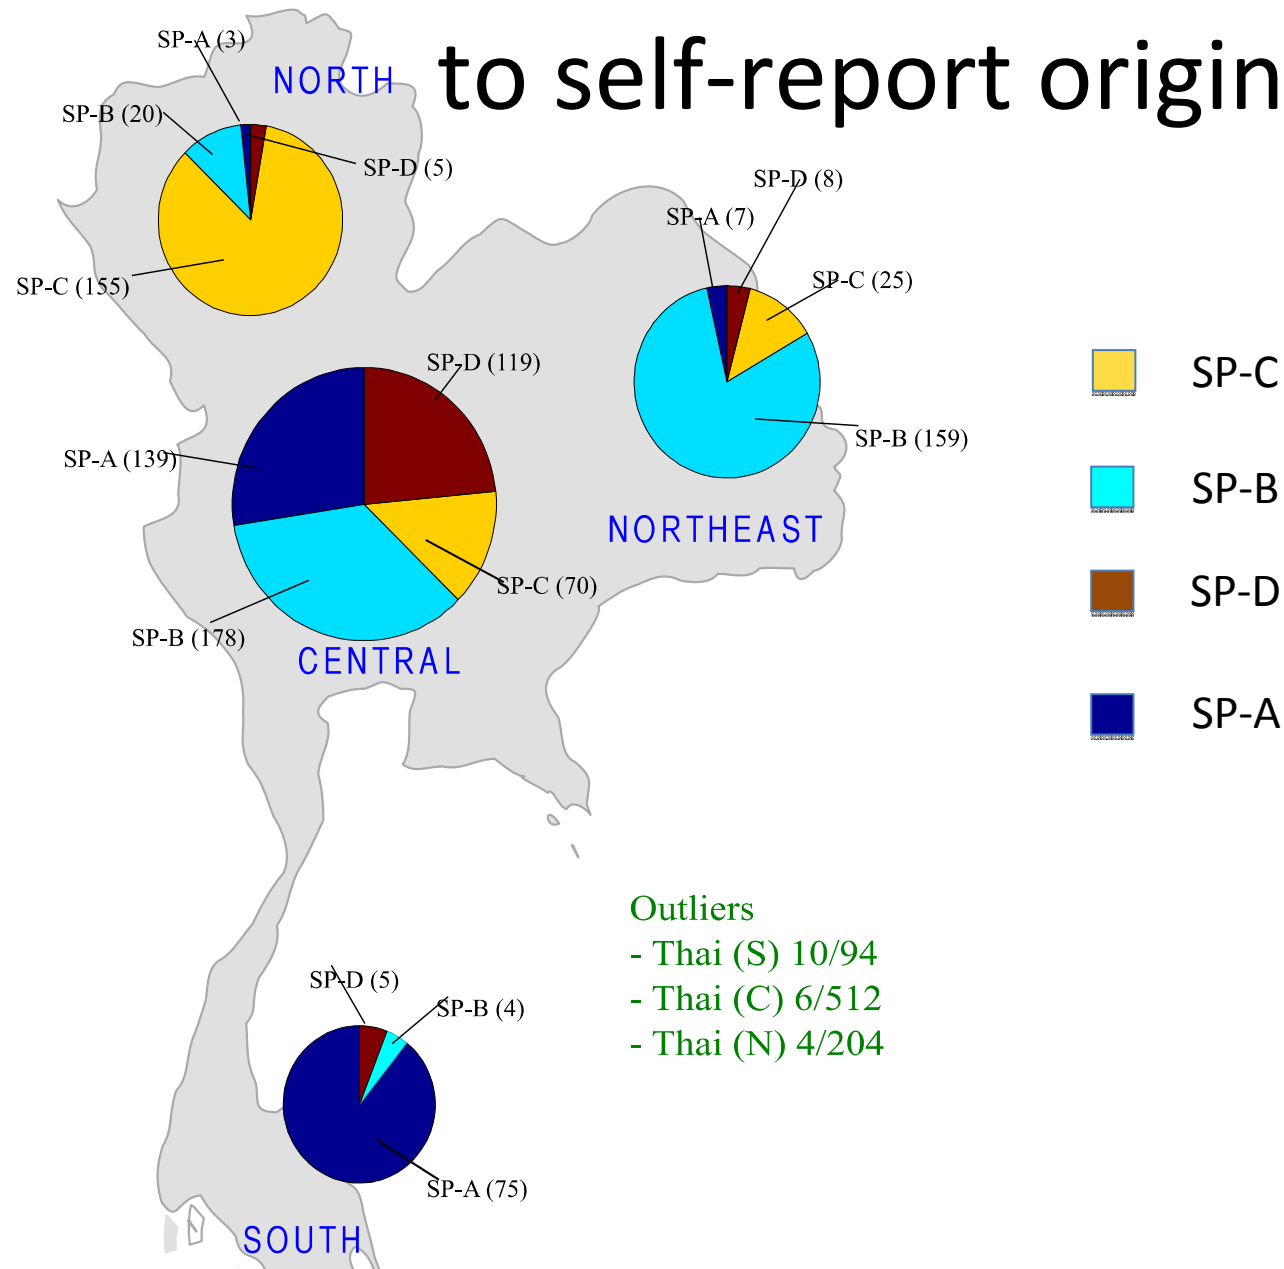

- Grouping according to genetic affiliation
- Some individuals were assigned to different countries.

# Thai subpopulations resolved by ipPCA

# Subpopulation distributions according to self-report origins

# Discriminative SNPs

- Are there SNPs that can differentiate any two subpopulations, e.g., SP-A vs SP-B or -C or -D
- Phenotype-Genotype??

### A Genomewide Association Study of Skin Pigmentation in a South Asian Population

Renee P. Stokowski, P. V. Krishna Pant, Tony Dadd, Amelia Fereday, David A. Hinds, Carl Jarman, Wendy Filsell, Rebecca S. Ginger, Martin R. Green, Frans J. van der Ouderaa, and David R. Cox

We have conducted a multiteg genomic association study, using 1,620,742 single-nucleotide polymorphisms to systematically investigate the genetic factors influencing intrinsic skin pigmentation in a population of South Asian descent. Polymorphisms in three genes—*SLC24A5*, *TYR*, and *SLC45A2*—yielded highly significant replicated associations with skin reflectance measurements, an indirect measure of melanin content in the skin. The associations detected in these three genes, in an additive manner, collectively account for a large fraction of the natural variation of skin pigmentation in a South Asian population. Our study is the first to interrogate polymorphisms across the genome, to find genetic determinants of the natural variation of skin pigmentation within a human population.

Humans possess an impressive range of skin pigmentation, both within and between populations. This diversity is highly correlated with geographical location, indicating that environmental factors as well as genetics strongly influence skin color. The predominant environmental variable affecting skin pigmentation is sunlight, and it is certain that skin pigments play an important role in both protecting DNA from the effects of UV irradiation<sup>1,2</sup> and influencing the availability of UV radiation for the synthesis of necessary compounds, such as vitamin D.<sup>3,4</sup> Epidemiological studies in humans show that skin pigmentation is a polygenic quantitative trait with high herit-

mentation the same across different ethnic populations, and are there still-undiscovered pigmentation genes?

With the availability of the entire human genomic sequence in 2001,<sup>5,6</sup> the identification of millions of SNPs across the genome,<sup>7-11</sup> and the development of high-throughput genotyping technologies, the tools were available for investigation of the genetic components controlling human skin pigmentation with use of a high-density genomewide association study. In the present study, we applied a three-tiered methodology of quantitative pooled genotyping followed by individual genotyping of associated SNPs in original and replicate population

#### Abstract

Alcohol drinking is a major risk factor for esophageal cancer (EC) and the metabolism of ethanol has been suggested to play an important role in esophageal carcinogenesis. Epidemiologic studies, including genomewide association studies (GWAS), have identified single nucleotide polymorphisms (SNPs) in alcohol dehydrogenases (ADHs) and aldehyde dehydrogenases (ALDHs) to be associated with EC. Using a population-based case-control study with 858 EC cases and 1,081 controls conducted in Jiangsu Province, China, we aimed to provide further information on the association of ADH1B (rs1229984), ADH1C (rs698) and ALDH2 (rs671) polymorphisms with EC in a Chinese population. Results showed that ADH1B (rs1229984) was associated with EC with odds ratios (ORs) of 1.34 [95% confidence interval (CI): 1.08-1.66] in G-allele carriers compared to A/A homozygotes. No heterogeneity was detected on this association across different strata of alcohol drinking and tobacco smoking. Statistical interaction between ALDH2 (rs671) and alcohol drinking on EC susceptibility in both additive and

# Conclusions

- Individuals can be grouped into different “genetic affiliated” groups
- Global SNP patterns can be used to cluster individuals
- Such unique patterns can hint us more on local selection/adaptation
- Complex traits involve both Genetics as well as environmental factors
